Concepts in Practical Model Building

Concepts in practical model building

- Recoding variables
- Transformations
- Multicollinearity

LA Homes

What factors help explain the price of a home in Los Angeles?

Model building

We'd like to build a model to explain prices of homes in LA as a function of the characteristics of those homes.

$$\widehat{price} = location + size + pool + acreage \dots$$

- 1. Statistical question
- 2. Data wrangling
- 3. Exploratory Data Analysis
- 4. Modeling
- 5. Interpretation

Consider: exploratory vs. confirmatory analysis.

Data wrangling

Home price data is available on many websites now, including zillow.com.

```
LA <- read.csv("../files/LA.csv")
head(LA)
```

```
##
         city type bed bath garage sqft pool spa price
## 1 Long Beach
                                  513
                                           NA 119000
## 2 Long Beach
                                  550
                                           NA 153000
## 3 Long Beach
                                  550
                                           NA 205000
                    0 1 1 1030
## 4 Long Beach
                                           NA 300000
## 5 Long Beach
                         1
                               1 1526
                                           NA 375000
## 6 Long Beach
                                  552
                                           NA 159900
```

Unit of observation: a home for sale in west LA.

Population: all homes in west LA.

Data wrangling, cont.

```
str(LA)
## 'data.frame': 1594 obs. of 9 variables:
   $ city : Factor w/ 4 levels "Beverly Hills",..: 2 2 2 2 2 2 2 2 2 2
   $ type : Factor w/ 3 levels "","Condo/Twh",..: 1 1 1 1 1 1 1 1 1 1
##
## $ bed : int 0 0 0 0 0 1 1 1 1 1 ...
## $ bath : num 1 1 1 1 1 1 1 1 1 ...
## $ garage: Factor w/ 5 levels "","1","2","3",..: 1 1 1 2 2 1 1 1 1 1 .
## $ sqft : int 513 550 550 1030 1526 552 558 596 744 750 ...
## $ pool : Factor w/ 2 levels "","Y": 1 1 1 1 1 1 1 1 1 1 ...
## $ spa : logi NA NA NA NA NA ...
   $ price : num 119000 153000 205000 300000 375000 ...
##
levels(LA$city)
```

[1] "Beverly Hills" "Long Beach" "Santa Monica" "Westwood"

Recoding type

The levels of a categorical variable can be queried using levels().

```
levels(LA$type)
                   "Condo/Twh" "SFR"
## [1] ""
LA <- LA %>%
  mutate(type = fct_recode(type,
                            "unknown" = "",
                            "condo" = "Condo/Twh",
                            "sfr" = "SFR"))
levels(LA$type) <- c("unknown", "condo", "sfr")</pre>
levels(LA$type)
## [1] "unknown" "condo" "sfr"
```

Recoding garage

```
str(LA)
```

What's going on with garage?

Recoding garage, cont.

```
levels(LA$garage)
         "1" "2" "3" "4+"
## [1]
      11 11
count(LA, garage)
## # A tibble: 6 x 2
## garage n
## <fct> <int>
## 1 ""
             388
##
  2 "1"
             260
##
  3 "2"
             666
##
  4 "3"
           37
  5 "4+"
             6
##
## 6 <NA>
          237
```

Recoding garage, cont.

We can combine levels using a similar approach.

```
count(LA, garage)
```

```
## # A tibble: 3 x 2
## garage n
## <fct> <int>
## 1 small 648
## 2 large 709
## 3 <NA> 237
```

Data wrangling, cont.

```
str(LA)
```

What's going on with pool and spa?

Dropping columns

Two variables seem mis-coded/uninformative, so they should be dropped.

```
LA <- select(LA, -pool, -spa)
```

Fully wrangled data set

```
head(LA)
```

```
## 1 Long Beach unknown 0 1 small 513 119000
## 2 Long Beach unknown 0 1 small 550 153000
## 3 Long Beach unknown 0 1 small 550 205000
## 4 Long Beach unknown 0 1 small 1030 300000
## 5 Long Beach unknown 0 1 small 1526 375000
## 6 Long Beach unknown 1 small 552 159900
```

Once the data set is ready to go, save it to a new .csv file.

```
write.csv(LA, file = "LA.csv")
```

Exploratory Data Analysis

Our goals are to:

- 1. Develop a sense of the *univariate* distributions in terms of center, shape, spread, unusual observations.
- 2. Develop a sense of the *bivariate* and *multivariate* distributions and what they indicate about the relationship between variables.

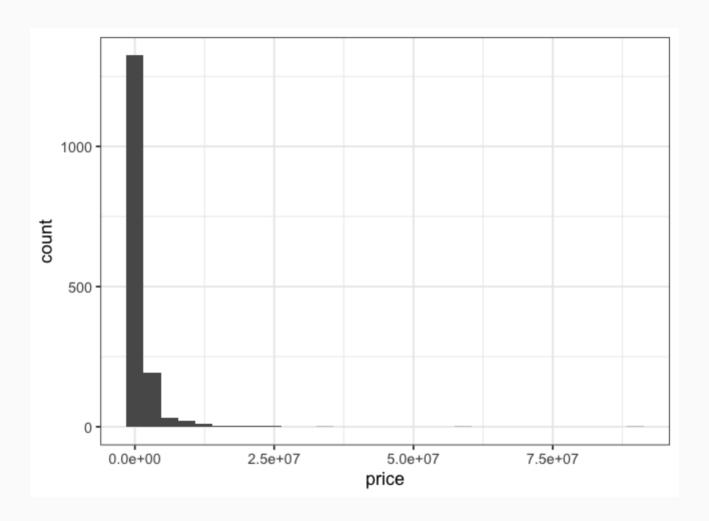

Which of the following are *not* good methods to visualize the distribution of a single variable?

- 1. mosaic plot
- 2. density plot
- 3. scatterplot
- 4. histogram
- 5. side-by-side boxplots

Which of the following at *not* good methods to visualize the distribution of a single variable?

- 1. mosaic plot
- 2. density plot
- 3. scatterplot
- 4. histogram
- 5. side-by-side boxplots

EDA for price

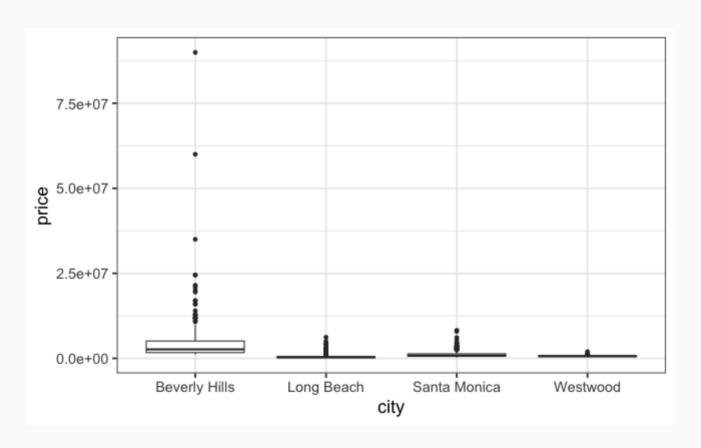

How would you visualize the relationship between price and city?

```
head(LA)
```

```
## city type bed bath garage sqft price
## 1 Long Beach unknown 0 1 small 513 119000
## 2 Long Beach unknown 0 1 small 550 153000
## 3 Long Beach unknown 0 1 small 550 205000
## 4 Long Beach unknown 0 1 small 1030 300000
## 5 Long Beach unknown 0 1 small 1526 375000
## 6 Long Beach unknown 1 small 552 159900
```

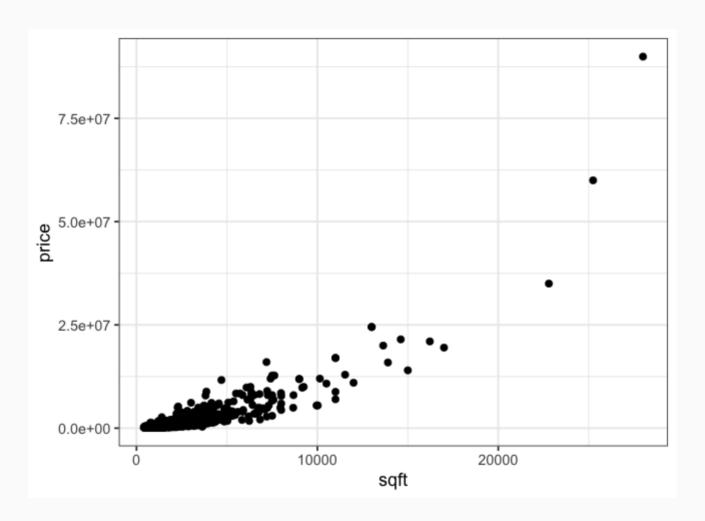

How would you visualize the relationship between price and city?

How would you visualize the relationship between price and sqft?

```
head(LA)
```

```
## city type bed bath garage sqft price
## 1 Long Beach unknown 0 1 small 513 119000
## 2 Long Beach unknown 0 1 small 550 153000
## 3 Long Beach unknown 0 1 small 550 205000
## 4 Long Beach unknown 0 1 small 1030 300000
## 5 Long Beach unknown 0 1 small 1526 375000
## 6 Long Beach unknown 1 small 552 159900
```

Transformations

Highly skewed data (particularly the response) can be very difficult to model using least squares regression. A common solution is to consider a transformation of the variable.

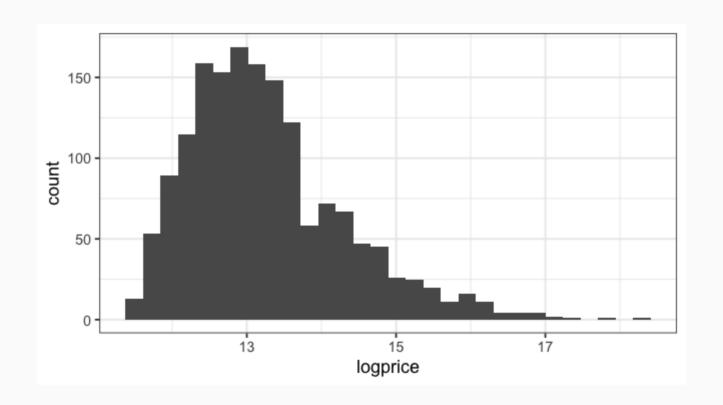

$$\widehat{price} \sim sqft$$

versus

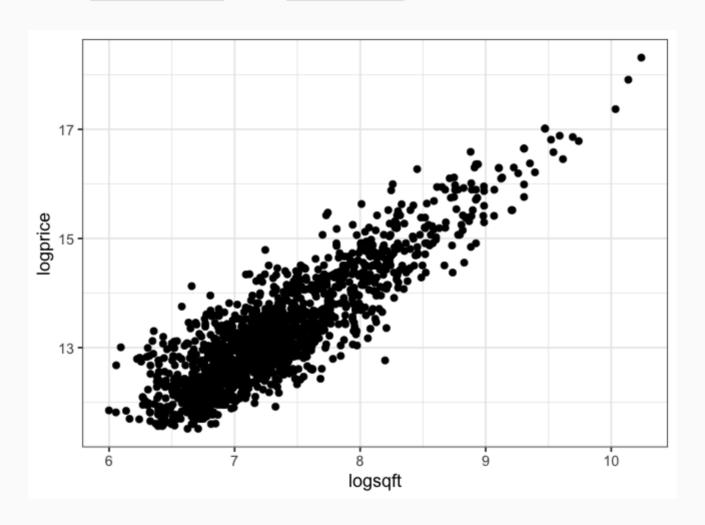

$$\widehat{log(price)} \sim log(sqft)$$

EDA for price

```
LA <- LA %>%
mutate(logprice = log(price))
```

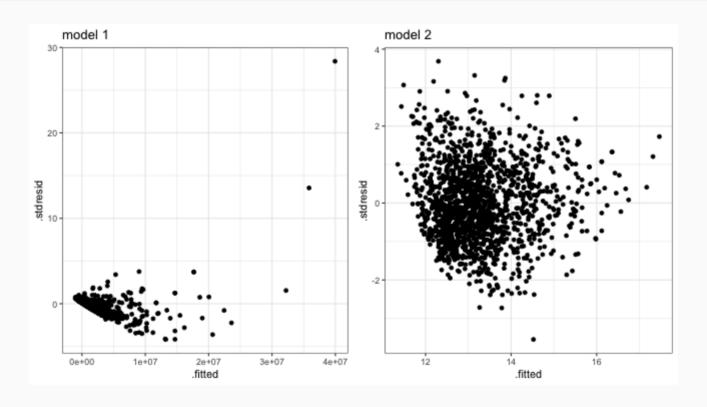

EDA for logprice and logsqft

Comparing residuals

```
m1 <- lm(price ~ sqft, data = LA)
m2 <- lm(logprice ~ logsqft, data = LA)</pre>
```

Transformation, cont.

Highly skewed data often leads to invalid models. This can be often be fixed with a transformation, but the interpretations change slightly.

```
## Estimate Std. Error t value Pr(>|t|)
## (Intercept) 2.70 0.1437 18.8 1.97e-71
## logsqft 1.44 0.0195 73.8 0.00e+00
```

A one unit increase in the log sqft of a home is associated with a 1.44 unit increase in the log price of a home.

Modeling: a simple model for price

$$\widehat{log(price)} \sim bed$$

```
m3 <- lm(logprice ~ bed, data = LA)
```

What do you expect the *sign* of the slope for bed to be?

```
summary(m3)$coef
```

```
## (Intercept) 11.802 0.0436 270.6 0.00e+00  
## bed 0.532 0.0142 37.3 9.77e-220
```

A less simple model for price

$$\widehat{log(price)} \sim bed + log(sqft)$$

```
m4 <- lm(log(price) ~ bed + logsqft, data = LA)
```

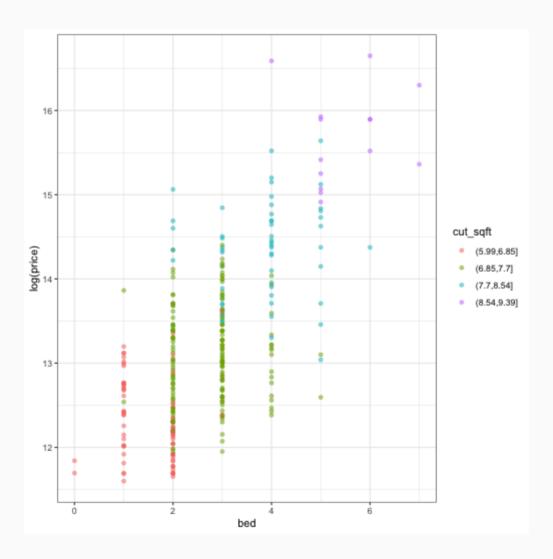

What do you expect the *sign* of the slope for bed and logsqft to be?

```
summary(m4)$coef
```

```
## (Intercept) 1.467 0.2178 6.73 2.28e-11
## bed -0.123 0.0164 -7.46 1.46e-13
## logsqft 1.656 0.0346 47.85 2.60e-310
```

Simpson's Paradox

Simpson's Paradox

Another wrinkle: Multicollinearity

Multicollinearity

Correlation between the predictors has some important consequences:

- 1. Addition or removal of correlated predictors can lead to slope sign changes.
- 2. Correlation between the predictors leads to an inflated $SE(b_1)$.

In sum: multicollinearity leads to **instability** in your estimates.

The SE of the slope

In the case of a MLR model with two correlated predictors,

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \epsilon$$

If $r_{1,2}$ is the correlation between X_1 and X_2 , then.

$$SE(b_i) \propto rac{\sigma}{1-r_{1.2}}$$

Multicollinearity

Take-home lesson: if your predictors are correlated, then they're carrying the same information about the response and your model with have a difficult time attributing explanatory power to this variable or that.

One approach: remove one/some of the correlated predictors.

Another approach: get more data to lower the SE.
